

COMPUTER AND NETWORK SECURITY

Edoardo Puglisi

Goals:

- Cryptography: encryption, authentication & integrity, digital signatures  
- Security protocols: TLS (https), SSH, IPsec 
- Firewalls 

INFORMATION SECURITY (aka INFOSEC)

Safety - prevent unintentional accidents (maybe by people)

Security = prevent malicious activities by people

Infosec is the protection of confidentiality, integrity, availability, the protection of information and information systems from unauthorized access, use, disclosure, disruption, modification or destruction.

We will cover only confidentiality and integrity.

Security differs from cryptography because it deals most of the times with fraud problems (message modification, user auth.) and not with secrecy of informations (it may use cryptography anyway)

Encryption

Given an E encryption function with key k_1 and a D decryption function with key k_2 , for every message m : $D_{k_2}(E_{k_1}(m)) = m$

It can be symmetric (secret key $k_1 = k_2$) or asymmetric (public key $k_1 \neq k_2$)

Threat: something that is a source of danger

Exploit: software, data, sequence of commands that take advantages of a vulnerability

Within a communication between two user may be an adversary: passive if it only read messages between them, active if can modify it or send new ones as one of the two users (identity steal)

Security goal is to make hard (in computational sense) to find the key to decrypt the message so that no adversary can determine any meaningful information about it.

CIPHER

• Plaintext = message before encryption

• Ciphertext = message after encryption

Caesar's cipher and substitution cipher are easy to break (also thanks to statistical analysis of language).

Perfect Cipher: plaintext space = $\{0,1\}^n$, D known. Given a ciphertext C the probability that exists k_2 such $D_{k_2}(C) = P$ for any plaintext P is equal to the uniform probability that P is the plaintext \rightarrow ciphertext doesn't reveal any info of plaintext

$$P_k[P|C] = P_k[P]$$

$$[P_k[P|C] = P_k[P \wedge C] / P_k[C]] \rightarrow \text{definition of conditional probability}$$

$$[P_k[P \wedge C] = P_k[P|C] P_k[C] = P_k[C|P] P_k[P]] \rightarrow \text{Bayes Theorem}$$

ONE TIME PAD

Key K long at least as plain text $\rightarrow E_K(P) = C = P \oplus K$ \oplus = OR exclusive bit by bit K chosen at random.

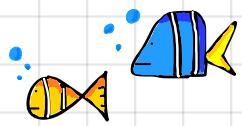

$$D_K(C) = C \oplus K = P \oplus K \oplus K = P$$

Key must be used one time only \rightarrow Key stream.

OTP is a perfect cipher but has issue of key space

Shannon Th.: a cipher cannot be perfect if key space size is less than message space size. (\neq key or message length)

ATTACK MODELS

Eavesdropping: listen to private conversation without consent (passive)

Known Plaintext: attacker knows plain and encrypted text and can reveal secret info. such as secret keys.

Chosen Plaintext: attacker can choose the plaintext to be encrypted so that he can reveal more info about encryption scheme.

Adaptive chosen plaintext: sequences of plaintext depending on the previous one (encryptions)

Chosen Ciphertext: symmetric to chosen plaintext

Physical Access

"Physical" modification of messages.

STREAM CIPHER

Define a secret key named **seed**. Using seed generate a byte stream named **Keystream**: i^{th} byte can be function of

① only seed → **synchronous stream cipher**; or

② seed and first $i-1$ bytes of ciphertext → **asynchronous stream cipher**

Obtain ciphertext by bitwise xorring plaintext and Keystream

Famous stream cipher is RC-4. All are inspired from creative pool.

The only thing attackers can easily get is the length → compress plaintext (like zip.)

BLOCK CIPHER

Symmetric. Plaintext with constant size (b bit) called **block**. Usually $b=64$ or 128 bits. Ciphertext will be a function of $P(\text{block})$ and K (key, also fixed bits) of b bits.

Big files can be divided in multiple blocks producing multiple ciphertext blocks and then unite them.

If file's length isn't a block size multiple we have to deal with the rest → add some padding

Some situation if file's size doesn't reach 1 block length.

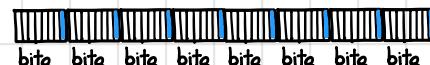

Problems:

① Many encryptions →

② Need many encryptions (usually hardware) → Need Money! 💰

DES = well known block cipher, now completely broken.

↳ 56 bits, apparently 64 bit but every last bit of the 8 bytes is a parity bit

BROKEN:

$|K|=n=\text{Key length} \rightarrow 2^n \text{ possible keys}$

If you find a way to use less 2^n attempts the algorithm is considered broken but may be still secure.

Rijndael: 128 bit block, 128-256 bit key → Advanced Encryption Standard (AES)

AES: x

↙ round key

Every round uses a piece of key e.g. 128 bits divided in pieces of 32bit → 4 rounds

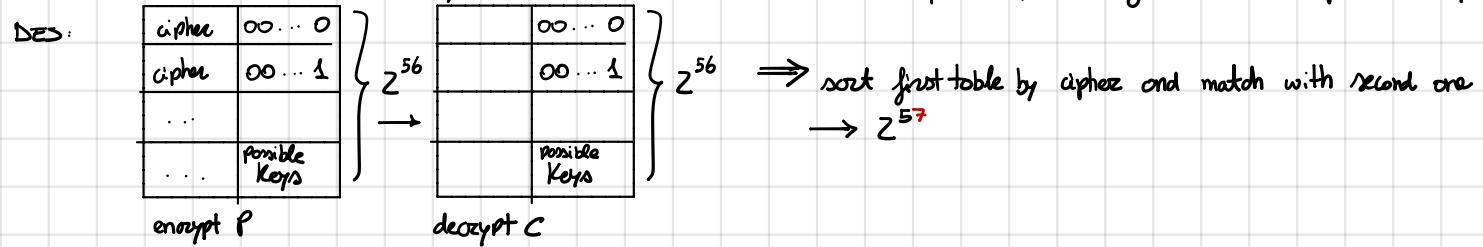

Key schedule: algorithm that generates a long key from the starting key.

CIPHER STRENGTHENING

Encrypting multiple times is useless if you use the same key.

What if: plaintext $\rightarrow \text{DES} \rightarrow \text{DES} \rightarrow C$ is it the same as a 112 bit encryption (56×2)? No

Meet-in-the-middle: Man in the middle: attacker knows a pair (P, C) . Imagine (P, C) was produced by double DES:

3-DES? Combine first 2 encryption $\rightarrow Z^{12}$ size table \rightarrow harder but possible ... in future.

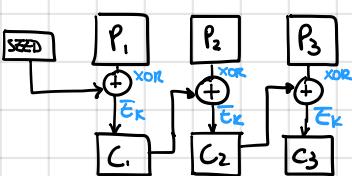

ELECTRONIC CODE BLOCK (ECB)

Separately encrypt each plaintext block in parallel reducing time (if space available etc.)

Something for decryption: What if attackers change 1 bit of ciphertext (more exposed), data integrity problem?

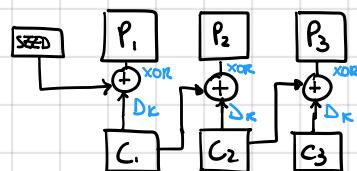

All blocks unaffected by change will be decrypted, the other will be completely useless (garbage)!

CBCHothing

Seed = (random) string to start the process.

Change on 1 Cipherblock will effect both its Plaintext and the next one: the second one 1 bit error only, the first one will be completely useless. \rightarrow error detecting code (CRC)

Encryption can't be done in parallel. Decryption instead can be done in parallel. In most of the cases # decryption > # encrypt.

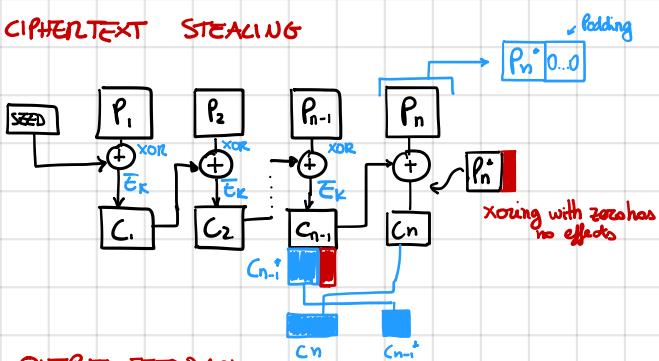

Seed is shared between sender and receiver and NOT encrypted \rightarrow OPEN security

Encrypting seed is not wrong anyway, just more work to do! Change it every now and then

To encrypt a seed CBC \approx ECB: for a single block seed, CBC just a little more secure cause need a seed to encrypt it.

CBC acts like an asynchronous stream cipher.

CIPHERTEXT STEALING

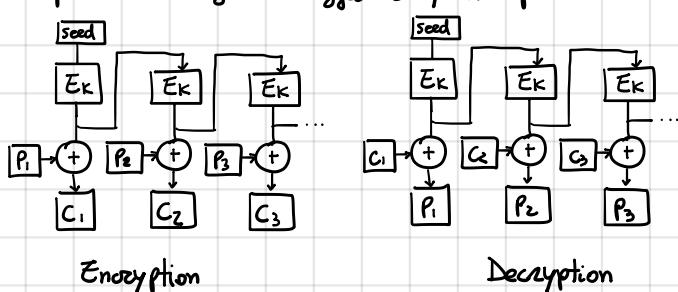

OUTPUT FEEDBACK

It acts like a synchronous stream cipher. Both encryptor and decryptor schemes use encryptor

Ciphertext modification effect only one plaintext block.

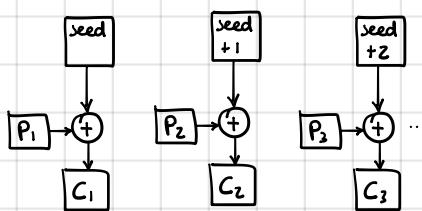

Used to avoid padding. The process for all but two last blocks is the same. Part of the second-last ciphertext is "stolen" to pad the last plaintext block. Then swap C_n and C_{n-1} position

Encryption

Decryption

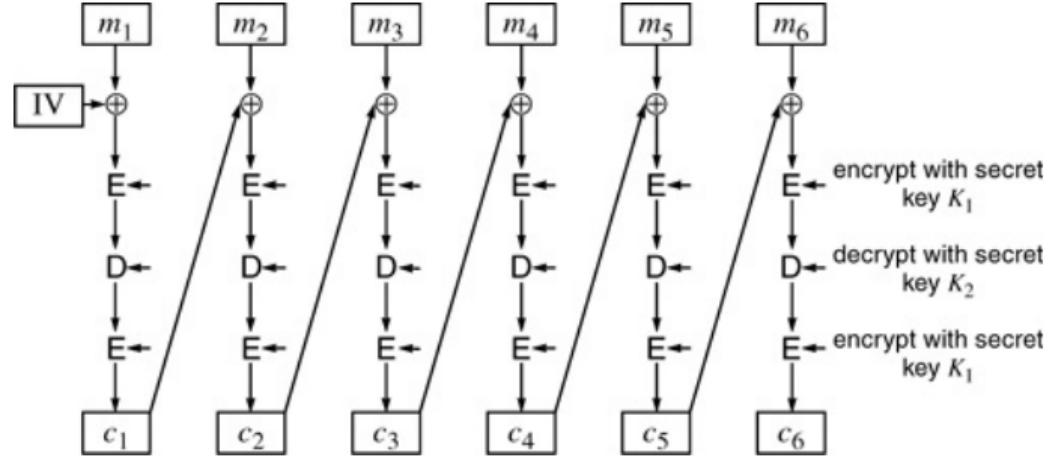

COUNTER MODE (CTR)

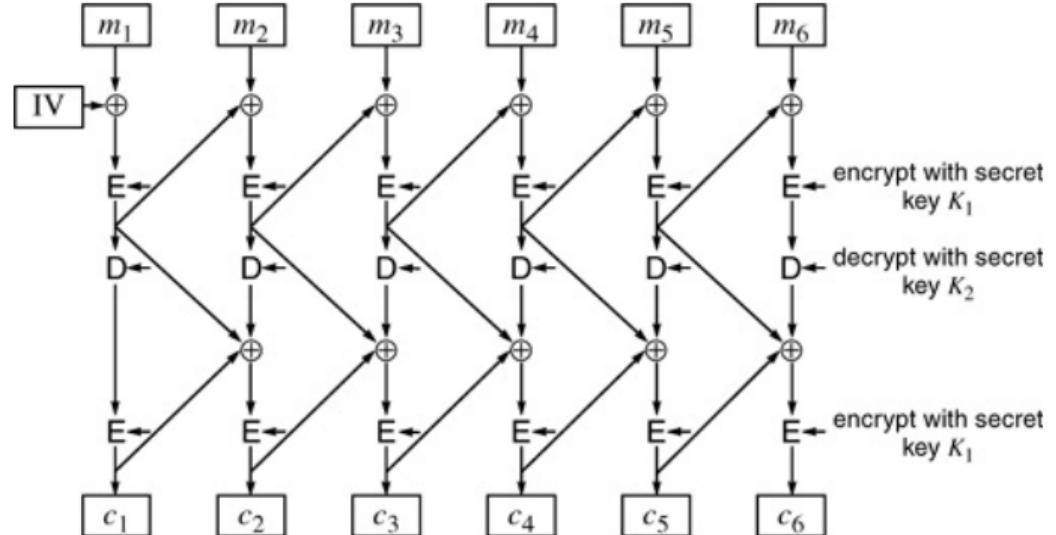

Fix repeated use of same seed like OFB
We can decrypt starting from any block.

Other possible modes are **Triple Encoding + CBC** = CBC with 3 consequent encryption (and 3 different keys) or **Internal / External EDE CBC**.

Outside EDE CBC

Inside EDE CBC

GROUPS

A **commutative (Abelian) group** is a set G with a binary operation $+$ with following properties:

- ① $\forall a, b \in G \quad a+b \in G \rightarrow G$ closed under $+$
- ② $\forall a, b, c \in G \quad (a+b)+c = a+(b+c) \rightarrow$ associative
- ③ $\forall a, b \in G \quad a+b = b+a \rightarrow$ commutative
- ④ $\exists 0 \in G \quad \forall a \in G \quad a+0=a \rightarrow$ identity element
- ⑤ $\forall a \in G \quad \exists -a \in G \quad a+(-a)=0 \rightarrow$ inverse element

$\downarrow \rightarrow$ change $+, 0, -a$ with $\cdot, 1, 0$ for multiplication

$(H, +)$ is a subset of $(G, +)$ if it is a group and $H \subseteq G$

↳ **Lagrange Th.**: if G finite and $(H, +)$ subgroup of $(G, +)$ then $|H|$ divides $|G|$

$\downarrow a$ and b congruent modulo n

$a \equiv b \pmod{n}$ if $|a-b|$ is multiple of n i.e. integer division of a and n and both n have same remainder.

\mathbb{Z}_n = quotient set of n classes of equivalence congruent to $0, 1, \dots, n-1 \rightarrow -1 \equiv n-1 \pmod{n}, -2 \equiv n-2 \pmod{n}, \dots$

• if $a \equiv b \pmod{n} \rightarrow a+c \equiv b+c \pmod{n}$

• if $a \equiv b \pmod{n} \rightarrow a \cdot c \equiv b \cdot c \pmod{n}$

• if $a \equiv b \pmod{n} \rightarrow a^c \equiv b^c \pmod{n}$

ORDER OF ELEMENTS

a^n denotes $a+a+\dots+a$ (n times, $aaa\dots$ if multiplicative operator). a is of order n if $a^n=0$ and $\forall m < n \quad a^m \neq 0$

($a^n=1$ for multiplicative operator) \rightarrow all elements of finite group have finite order.

\mathbb{Z}_m = natural numbers mod n - classes of equivalence of congruent integers \pmod{n}

\mathbb{Z}_m^* = natural numbers mod n prime (co-prime) to m (multiplicative group of \mathbb{Z}_m)

ϕ_m = Euler's totient function $= |\mathbb{Z}_m^*|$

→ Euler th.: $\forall a \in \mathbb{Z}_m^* \quad a^{\phi(m)} \equiv 1 \pmod{m} \rightarrow a^{k\phi(m)+1} = a \pmod{m} \quad k \geq 0$

I $a \in G$ and $\langle a \rangle = \{1, a, \dots, a^{n-1}\}$ sub-group of G then a = generator of $\langle a \rangle$, G = cyclic group and a = primitive element of G

Th.: $\forall p$ prime the multiplicative group of \mathbb{Z}_p (\mathbb{Z}_p^*) is cyclic

A set F with two binary operation $+$ and \cdot is called commutative **ring** with identity if:

- ① $\forall a, b \in F \quad a+b \in F$
- ② $\forall a, b, c \in F \quad (a+b)+c = a+(b+c)$
- ③ $\forall a, b \in F \quad a+b = b+a$
- ④ $\exists 0 \in F \quad \forall a \in F \quad a+0=a$
- ⑤ $\forall a \in F \quad \exists -a \in F \quad a+(-a)=0$
- ⑥ $\forall a, b \in F \quad a \cdot b \in F$
- ⑦ $\forall a, b, c \in F \quad (a \cdot b) \cdot c = a \cdot (b \cdot c)$
- ⑧ $\forall a, b \in F \quad a \cdot b = b \cdot a$
- ⑨ $\exists 1 \in F \quad \forall a \in F \quad a \cdot 1 = a$
- ⑩ $\forall a, b, c \in F \quad a \cdot (b+c) = a \cdot b + a \cdot c$

It's called **field** if we add relation ⑪ $\forall a \neq 0 \in F \quad \exists a^{-1} \in F \quad a \cdot a^{-1} = 1 \rightarrow$ each nonzero element has a multiplicative inverse

let $f(x) = a_n \cdot x^n + a_{n-1} \cdot x^{n-1} + \dots + a_1 \cdot x + a_0$ over a field F ($a_n, a_{n-1}, \dots, a_0 \in F$) $\rightarrow f(x)$ has at most n solutions in F

Let $f(x)$ and $g(x) = b_m x^{m-1} + \dots + b_0$ ($m \leq n$) $\rightarrow f(x) = h(x) \cdot g(x) + r(x) \rightarrow r(x) = \text{remainder of } f(x) \pmod{g(x)}$ and it's unique.

$(F, +, \cdot)$ is finite field if $\text{ntk } F$ is finite.

GALOIS FIELD GF(p^k): \forall prime power p^k there is a unique finite field containing p^k elements denoted as $GF(p^k)$. No finite fields with other cardinalities

Let $f(x)$ irreducible polynomial of degree k over \mathbb{Z}_p $\rightarrow GF(p^k)$ can be realized as the set of $k-1$ polynomials over \mathbb{Z}_p with $+$ and \cdot done modulo $f(x)$

RIJNDAEL - AES

128 bit input/output block \rightarrow in 4×4 matrix of bytes

The matrix first contains plaintext then "converted" to ciphertext (some matrix)

Key (128, 192, 256...) in a matrix of $4 \times n / 32$ bytes

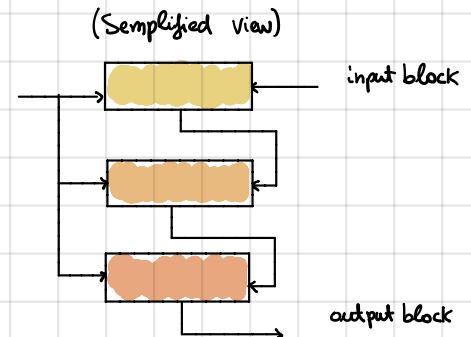

AES (plaintext, key)

- Key Expansion = Key expanded to 10 round keys (of key-length)
- AddRoundKey (State, ExpandedKey[i])
- Cycle ($i: 0 \rightarrow R$) Round (State, ExpandedKey[i])
- FinalRound (State, ExpandedKey[R])

(plaintext matrix)

A_{00}	A_{01}	A_{02}	A_{03}	...
A_{10}	A_{11}	A_{12}	A_{13}	
A_{20}	A_{21}	A_{22}	A_{23}	
A_{30}	A_{31}	A_{32}	A_{33}	
:				

Key

Every round has 4 steps:

① Substitution: $A_{i,j} = A_{i,j}^{-1}$ \rightarrow multiplicative inverse in $GF(2^8)$ highly non linear. If $A_{i,j}=0$ don't change. Invertible step.

② Shift Row: first row no shift, second row 1 shift, third row 2 shift ... Invertible step

③ Every column is considered as a polynomial over $GF(2^8)$ \rightarrow multiply with an invertible polynomial $03x^3 + 01x^2 + 01x + 02 \pmod{x^4 + 1}$

④ XOR with round key

For algorithm demo: <https://www.youtube.com/watch?v=gP4PqVGudtg>

DATA INTEGRITY

(Suppose we don't care anymore of confidentiality). Message received = message sent even with active adversary in the middle.

A = authentication algorithm paired to Verification algorithm V (accept/reject). Key shared

Message $m = (m, A_k(m))$ pair with $A_k(m)$ = authentication tag

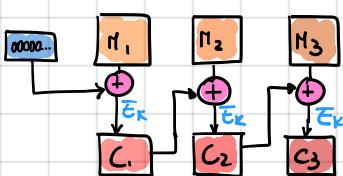

$V_k(m, A_k(m)) = \text{accept}$. A is usually called Message Authentication Code $\rightarrow A_k(m)$ denoted as $\text{MAC}_k(m) \rightarrow$ Verification by executing authentication on $A_k(m)$ and comparing with $\text{MAC}_k(m)$

Attacker can't (shouldn't) construct legal pair $(m, \text{MAC}_k(m))$ even after observing many legal pairs, output short, MAC function not 1-to-1 (more messages with same auth. tag).

EXISTENTIAL FORGERY: attack that produces a legal pair message-authentication tag even if meaningless for receiver

Given n legal pairs $(m_1, \text{MAC}_k(m_1))$ find a new legal pair $(m, \text{MAC}_k(m))$ efficiently and without negligible probability.

MAC on CBC

- All zero seed.
- Discard first $n-1$ blocks
- Send m, \dots, m_n and C_n as authentication tag $\text{MAC}_k(m) = C_n$

Note: we don't need to secret the message ONLY INTEGRITY

Pseudo Random Function: function that looks random \rightarrow if E_k is a pseudo random function then the fixed length CBC MAC is resilient to forgery.

Insure for variable length messages.

To have confidentiality and data integrity: produce $\text{MAC}_{k_1}(m)$ with CBC, produce n ciphertexts with $k_2 \rightarrow$ send ciphertexts and $\text{MAC}_{k_1}(m)$

HASH FUNCTION

Map large domains (messages) to smaller (keys). MAC must be a function of message and key. e.g. $\text{MAC}_k(m) = h(k||m) \vee h(k||m||k) \dots [|| = \text{concatenation}]$

Collision Resistance: $h: D \rightarrow R$ is **weakly collision resistant** if it's hard to find $x \neq x'$ such that $h(x) = h(x')$ for $x \in D$. It's **strongly collision resistant** if it's hard to find x, x' such that $x \neq x'$ but $h(x) = h(x')$. STRONG \Rightarrow WEAK WEAK $\not\Rightarrow$ STRONG

Pre-Image Resistance: given authentication tag is hard to find the message i.e. given $h(x)$ is hard to find x . **Second Pre-Image resistance** if its hard to find a collision to x given $h(x)$

Summary: why hash function is cryptographic secure?

- **strong collision resistance**: hard to find pair $x \neq x'$ such that $h(x) = h(x')$ \Rightarrow weak collision resistance

- **Pre-image resistance**: given $h(x)$ is hard to find x

- **Second pre-image resistance**: given $h(x)$ is hard to find $x' \neq x$ such that $h(x') = h(x)$ (collision)

COLLISION ATTACK: attacker (man in the middle) sends a different message that still match authentication tag.

BIRTHDAY PARADOX

Given 23 persons 2 of them have same birthday with probability $\Pr > \frac{1}{2} \rightarrow$ thinking of it as an hash function is not so hard to find a collision

This "paradox" affects all hashing function, even the good ones. Anyway generating a message that collides is still difficult.

The probability depends only on range(R) size! \rightarrow e.g. $(1.1774|R|)^{\frac{1}{2}}$ elements of $D \rightarrow \Pr = 0.5$

BIRTHDAY ATTACK: given f find $x_1 \neq x_2$ such that $f(x_1) = f(x_2) \rightarrow$ e.g. 64bit hash means 1.8×10^{19} different output $\rightarrow 5.38 \times 10^9$ attempts to generate a collision using brute force (5.1×10^9 makes the probability to 0.5) \rightarrow # of attempts = **birthday bound** \sim (asymptotically) $\sqrt{|R|}$

ATTACK EXAMPLE:

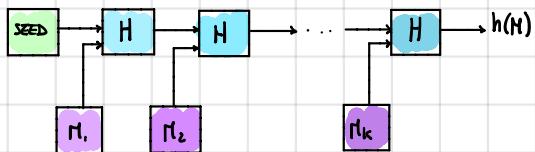

- generate "many" copies of message with small variation like adding spaces N "equivalent" copies.

- generate N copies of the fake message

- pick at random pairs from edited and fake messages. If hash has small numbers of bit it will be easy to find a match

Hash function have key (**Keyed**) or not (**Unkeyed**)

To deal with longer strings:

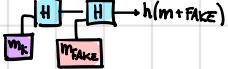

Merkle-Damgård construction

$h \neq H$, $H: D \rightarrow R$. Using this architecture (and if good) we create a cryptographically secure h .

If H is collision resistant then h will be too

Keyed hashing = $MAC_k(m) = \text{hash of key and message}$ guarantees also **authenticity** cause only the ones with the key can compute the hash
Prepending key to message ($k|m$) is a bad choice with previous architecture cause attacker could append a new block to m_k and generate a valid authentication tag without knowing the key.

APPEND KEY: ✗

case: key length = block length : attacker focus on $m - m_{k-1}$ blocks and try to find a colliding message **small vulnerability** (lot of work for attacker)
PREPEND & APPEND : $h(k|m|k)$, no vulnerability found. ✓

Modern hash functions compute more round for each block in which they swap, shuffle and some other atomic things to messages bits.

HMAC

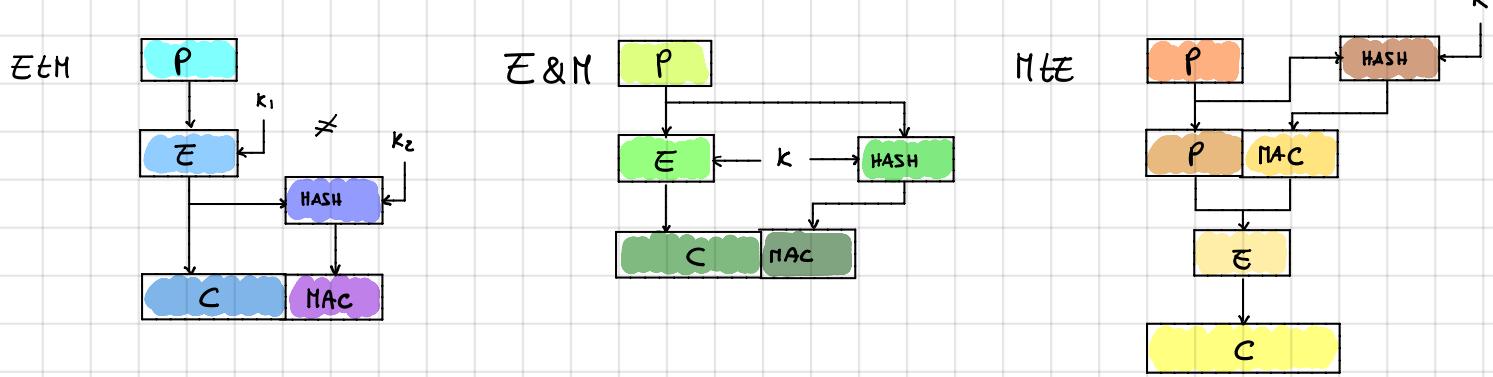

$HMAC_k(m, h) = h(k \oplus opad \parallel h(k \oplus ipad \parallel m))$ opad = outerpad = $0x5c5c\dots$ ipad = innerpad = $0x3636\dots$ both one-block long

HMAC can be forged only if h can be forged (by attackers)

AUTHENTICATED ENCRYPTION (AE)

Confidentiality + authenticity

- ① Encrypt - then - MAC (E-t-M) ② Encrypt and MAC (E&M) ③ MAC then Encrypt (M-t-E)
- ↳ most secure!

SALT: random string concatenated to (usually) a password to have a more robust password.

PUBLIC-KEY CRYPTOGRAPHY

New method. Secret-Key (cryptography is still new and good anyway (symmetric / asymmetric))!

The problem with symmetric encryption is that the key must be secretly generated and exchanged a prior in a unsecure channel!

DIFFIE & HELLMAN: Split key K in two: K_E used to encrypt, K_D to decrypt, K_E must be public \rightarrow public-key asymmetric.

The sender will encrypt messages with receiver's publickey (K_E) that will decrypt with his privatekey (K_D).

The owner of private key can encrypt with his own secret key so everybody can decrypt using the publickey. In this way we don't have confidentiality but we gain authentication cause only the owner of private key could have encrypted the message.

DISCRETE LOG: given $y = g^x$ with x minimal non negative integer satisfying the equation. x is called discrete log of y to base g . (g generator of G = finite cyclic group of n elements $\wedge y \in G$)
 $\rightarrow y = g^x \bmod p$ in multiplicative group of \mathbb{Z}_p^*

$x \rightarrow g^x \bmod p$ is easy with quick exponentiation but hard to reverse ($g^x \bmod p \rightarrow x$) $\Rightarrow x \rightarrow g^x \bmod p$ is believed to be a one-way function!

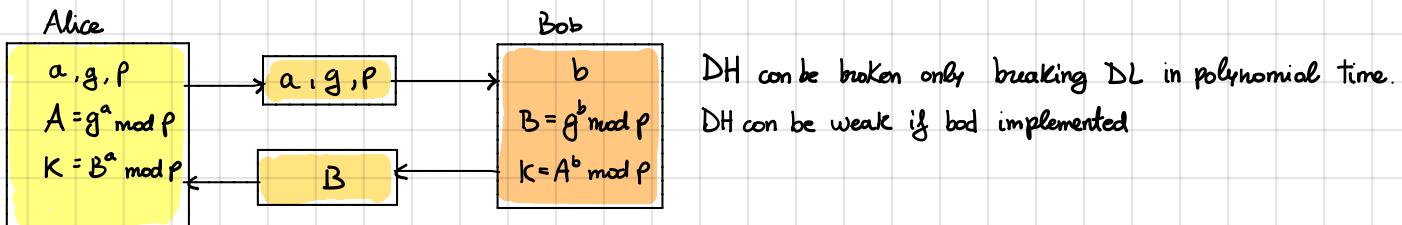

$f: \{0,1\}^n \rightarrow \{0,1\}^n$ is one-way if f can be computed in polynomial time, but for every polynomial-time algorithm (even randomized) A , for every polynomial $p(n)$ and all sufficiently large n : $\Pr[f(A(f(x))) = f(x)] < 1/p(n) \Rightarrow$ hard to reverse in the average-case!

These fucking functions are just theoretical, conjectured to exist! 😈

PUBLIC EXCHANGE OF KEY: two parties who don't share any secret information, perform a protocol and derive the same shared key.

DIFFIE - HELLMAN KEY EXCHANGE (DH): Alice — Bob

- Public parameters: prime p and an element g (possibly generator of \mathbb{Z}_p^*). p should be a safe prime $\rightarrow p = 2q + 1$ with q prime too.
- Alice chooses "a" at random in $[1 \dots p-1]$ and sends $g^a \bmod p$ to Bob. "a" secret.
- Bob chooses "b" at random in $[1 \dots p-1]$ and sends $g^b \bmod p$ to Alice. "b" secret
- Both compute $g^{ab} \bmod p$ or shared key. (e.g. Alice: $(g^b)^a \bmod p = g^{ab} \bmod p$)

Perfect Forward Secrecy: generate random public key per session for the purpose of key agreement and don't use any sort of deterministic algorithm in doing so. \rightarrow compromise a shared key doesn't compromise other shared key. Session Key and Forward Secrecy

E.g. given $N \rightarrow h(N)$ then $h(h(N))$ for next session and so on. Compromising $h(N)$ will compromise only that session.

Non-in-the-middle can succeed if there is no authentication

Let p and q be 2 large primes. $N = p \cdot q$

Multiplicative group $\mathbb{Z}_N^* = \mathbb{Z}_{pq}^*$ contains all integers in $[1, pq-1]$ that are prime with p and q

In $[1, pq-1]$ there are $(p-1)$ multiples of q and $(q-1)$ multiples of p . The size of the group is $\phi(pq) = pq - (p-1) - (q-1) = pq - (p+q) + 1 = (p-1)(q-1)$ so by Euler's th. $\forall x \in \mathbb{Z}_{pq}^*, x^{\frac{(p-1)(q-1)}{1}} = 1$

Exponentiation in \mathbb{Z}_{pq}^* : we want to exponentiate for encryption. Not all integers in $[1, pq-1]$ belong to \mathbb{Z}_{pq}^*

Given $1 < e < (p-1)(q-1)$ when exponentiation to e -th power a one-to-one operation in \mathbb{Z}_{pq}^* ? e.g. $x \rightarrow x^e$ with $x = \text{plaintext}$

\Rightarrow if e is relatively prime to $(p-1)(q-1)$ then $x \rightarrow x^e$ is a one-to-one operation in \mathbb{Z}_{pq}^*

RSA Public key Cryptosystem

- $N = pq$
- Choose $1 < e < \phi(N)$ s.t. $\gcd(e, \phi(N)) = 1$ gcd = greatest common divisor
- d s.t. $d \cdot e \equiv 1 \pmod{\phi(N)}$
- Public Key = (e, N)
- Private Key = (d, N)

\Rightarrow Encryption of $M \in \mathbb{Z}_N$ by $C = E(M) = M^e \pmod{N}$

Note different from DH solution to key distribution

\Rightarrow Decryption of $C \in \mathbb{Z}_N$ by $M = D(C) = C^d \pmod{N}$

RSA is mostly used to encrypt a secret symmetric key. Not used in practice for long messages.

EUCLID ALGORITHM $\rightarrow \text{GCD}(x, y)$

$x \geq y$. $\gcd(x, y) = \gcd(x-y, y)$ because x and y are integers $\rightarrow \frac{x-y}{d}$ is an integer too

Repeat the replace of the greatest one with the difference until $\begin{cases} \gcd(z, z) = z \\ \gcd(z, 0) = z \end{cases}$

$\gcd(1000, 2) \rightarrow ((1000-2)-2) - 2 \dots$ long time!

$\gcd(x, y) = \gcd(y, x \bmod y) \dots$

Let $p = 47$ $q = 53$ $N = pq = 273$ $\phi(N) = 46 \cdot 52 = 2668 \rightarrow$ choose $d = 157$

Bezout's identity: $xu + vy = d$ with $x \geq y$, u and v signed integers and $d = \gcd(x, y)$. x and y are given!

If x and y are coprime $\rightarrow d = 1 \rightarrow u = \text{multiplicative inverse of } x \pmod{y}$ and $v = \text{multiplicative inverse of } y \pmod{x}$

Traditional Euclid's alg. computes $\gcd(x, y)$ calculating $r_n = r_{n-2} \dots r_1, r_0$ with $r_2 = x$ $r_1 = y$ until $r_n = 0 \rightarrow r_{n-1} = \gcd$

Bezout's identity: exists u, v s.t. $ux + vy = 1$

Euclid's algorithm can be extended such that it computes the gcd of a and b + the coefficients of Bezout identity which are integers s.t. $ax + by = \gcd(a, b)$

Constructing an instance of RSA

- Alice picks at random coprimes p and q (large) $\rightarrow N = pq$
- Alice picks at random a large d relatively prime to $\phi(N) = (p-1)(q-1) \rightarrow \gcd(d, \phi(N)) = 1$
- Alice computes e s.t. $d \cdot e \equiv 1 \pmod{\phi(N)}$
- Alice publishes public key (N, e) and keeps secret everything else ((N, d) = private key)

\rightarrow Large coprime p and q : random, hard to guess. In $[N, 2N]$ there are $\sim N / \ln N$ primes

\rightarrow we expect to find a prime of N bits every $\ln N$ attempts.

\rightarrow e suitable to have fast encoding: usually the min value possible $\rightarrow 3$

$$x \xrightarrow{\text{hard}} X^e \pmod{N}$$

$\xrightarrow{\text{easy}}$

$f: D \rightarrow R$ is a trapdoor one way function if there is a trapdoor s s.t.

① without knowledge of s , f is a one way function

② Given s , inverting f is easy.

Easy with trapdoor info(d)

Problems:

① If $m=0,1$ or $N-1 \rightarrow RSA(m)=m \Rightarrow$ zero, use salt

② If m and e small we might have $m^e < N \rightarrow m^e \bmod N = m^e \Rightarrow$ odd non zero bytes to avoid small messages

SALTING: add extra bits to original message and then encrypt \rightarrow how? On decrypt we should be able to distinguish original message from salt.

Robustness of RSA doesn't mean always robust

Attacker can factor $N=pq$ if p and q have bad properties. Recommended to choose them

- large (100 digits)
- not close together
- $(p-1)$ and $(q-1)$ have large prime factors (to foil Pollard's Rho algorithm)

Some messages can be easy to decode (e.g. ciphertext = plaintext, particular case)

Note: if we factor N we break RSA.

③ If attacker has two encoding of two similar messages s.t. $c_1 = m^3 \bmod N$ and $c_2 = (m+z)^3 \bmod N$

$$\rightarrow m = (c_2 + z c_1 - z) / (c_2 - c_1 + z), \text{ or}$$

m and $(am+b)$ similar \rightarrow more complex but similar to previous one

\Rightarrow choose large e (at least 5)

④ $e=3$ and send message to three different users with public keys $(3, n_1)$, $(3, n_2)$, $(3, n_3)$

Attacker knows public keys and $m^3 \bmod n_1$, $m^3 \bmod n_2$, $m^3 \bmod n_3$

He can compute with Chinese Remainder Theorem $m^3 \bmod (n_1 \cdot n_2 \cdot n_3)$

$$m < n_1, n_2, n_3 \rightarrow m^3 < n_1 \cdot n_2 \cdot n_3 \text{ and } m^3 \bmod n_1 \cdot n_2 \cdot n_3 = m^3 \rightarrow \sqrt[3]{m^3} = (\bar{m})$$

\Rightarrow Add random bytes to avoid equal messages

⑤ If message space is small, attacker can try all possible messages

\Rightarrow Add random string in message

⑥ If two users have same N but different e and d \rightarrow same p and q

One of the two could compute p and q from his e, d, N (tricky but possible) then can easily derive secret key of other user given his public key

\Rightarrow Each person choose his own N (prob. to have same N one very very low)

⑦ Multiplicative property of RSA

If $M = M_1 \cdot M_2 \rightarrow (M_1 \cdot M_2)^e \bmod N = ((M_1^e \bmod N) \cdot (M_2^e \bmod N)) \bmod N$ so an attacker can proceed using small messages

\rightarrow padding on small messages

⑧ Chosen Ciphertext Attack

Attacker wants to decrypt $C = M^e \bmod N$

- computes $X = (C \cdot 2^e) \bmod N$
- uses X as chosen ciphertext and ask oracle for $Y = X^d \bmod N$
but $X = (C \bmod N) \cdot (2^e \bmod N) = (M^e \bmod N) \cdot (2^e \bmod N) = (2M)^e \bmod N \rightarrow$ he got $Y = 2M$

Attacker T knows $C = M^e \bmod N$, randomly choose X and computes $c' = cX^e \bmod N$ and ask oracle to decode c' . T computes $(c')^d = c^d(X^e)^d = M^e \bmod N$
→ require that M needs to verify some requirements to have the oracle answering

RSA conclusion: given m join M and then apply RSA.

PKCS: Cryptography Standard → $m = 0 \| z \|$ at least 8 non zero bytes $\| 0 \| M$ (M original message)

... message less than N (first byte)

z = denotes encrypting of a message and m not small (1 denotes encrypting of dig. signature)

random bytes = some message to many people, space message large.

m length $\sim M$ length!

OAEP: padding scheme often used with RSA encryption. = optimal asymmetric encryption padding

It uses a pair of random oracles G and H (hash functions) to process the plaintext prior to asymmetric encryption. The goal is to add randomness used to convert deterministic encryption scheme into a probabilistic one and prevent partial decryption ("all or nothing")

n = # bits in RSA modulus

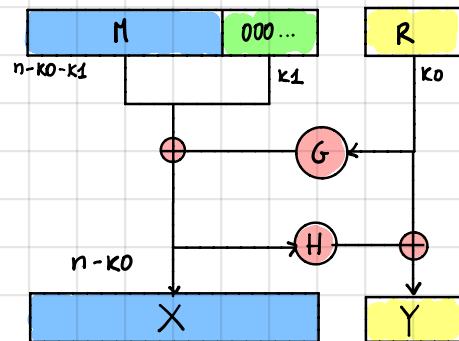

k_0 and k_1 = integers fixed by protocol

M = plaintext, $(n - k_0 - k_1)$ -bit string

G/H = hash functions fixed by protocol

ENCODE:

- messages padded with k_1 zeros → now $n - k_0$ length
- $R = n - k_0$ bit string
- G expands k_0 bits of R to $n - k_0$ bits
- $X = M 000\dots \text{xor } G(R)$
- H reduces the $n - k_0$ bits of X to k_0 bits
- $Y = R \text{ xor } H(X)$
- output $X \| Y$

DECODE

- recover random string $R = Y \text{ xor } H(X)$
- recover message $M 000\dots = X \text{ xor } G(R)$

RSA Encryption Schema - OAEP

- given M , determine encoded message M' (octet stream) by means of OAEP
- determine integer representative m of M' :
use $m = \text{OS2IP}(M') = \text{octet stream to integer primitive}$
- compute ciphertext representative (integer):
 $c = \text{RSAEP}((N, e), m)$ (N, e) is public key
- convert ciphertext representative to ciphertext (octet-stream):
use $C = \text{I2OSP}(c, \text{IN})$ integer to octet-stream primitive
- decryption is symmetric and is based on OAEP^{-1} and RSAEP

OS2IP: a non negative integer is constructed by interpreting k octets = 8-bit bytes as number in base 256.

Each octet is a digit (in $[0, 255]$). $k = \#$ bytes for representing N

I2OSP: An octet stream (array of k bytes) is constructed by determining the coefficient of representation in base 256 of the given integer. Each coefficient is an integer in $[0, 255]$ and is stored in one octet

ELGAMAL ENCRYPTION

Based on DH. 3 components: key generator, encryption and decryption algorithms.

Alice publish $p, g \in \mathbb{Z}_p$ as public parameters (g generator of cyclic group of order p)

Alice chooses x as private key and publish $g^x \bmod p$ as public key (x random in $[0, p-1]$)

Bob to Alice Encryption of $m \in \mathbb{Z}_p$ by sending $(g^y \bmod p, mg^{xy} \bmod p)$ (y random in $[0, p-1]$)

Decryption: Alice computes $(g^y)^x \bmod p = g^{xy} \bmod p$, then $(g^{xy})^{-1} \bmod p$ for obtaining $mg^{xy}(g^{xy})^{-1} \bmod p = m$

Requires two exponentiations per each block transmitted

Involves not trivial math.

DIGITAL SIGNATURES - DSA

HMAC/MAC can be generated by both Alice and Bob → we can have **repudiation** (Both says that they didn't send the message)

$$M \rightarrow S(M)$$

! → identify signer

→ use **Public Key Infrastructure**

Alice wants to produce a pair (M, S) that everybody can verify.

The signature will identify both the signer and the message!

→ change message/signer = change signature → can't copy signature

Candidate 1

$$M: (M, Enc(M)) = (M, S)$$

with Alice private key.

→ Bob receives (M, S) :

verify Dec. with public key of Alice and compare result with received M

This method is vulnerable to **forgery attack**: attacker is able to forge a pair (M, S) that pass the verification.

EXISTENTIAL forgery:

① Generate random file R

Verify

$$\text{Dec}_{\text{Pub}(A)}(R) = T$$

equal to T in (T, R) → ✓

② Construct $T = \text{Dec}_{\text{Pub}(A)}(R)$

③ Send (T, R)

Candidate 2

$(M, Enc_{\text{priv}(A)}(H(M)))$: use only cryptographically secure hash function **unkeyed**

Verification upon receiving:

$(M, S) \rightarrow$ compute $H(M) \checkmark \rightarrow \text{Dec}_{\text{Pub}(A)}(S) = H(M) \checkmark \rightarrow$ compare the two $H(M)$ ✓

For existential forgery the attacker should send (T', R) where $T' = H(T') \times \rightarrow$ hard if H cryptosecure.

This is the **Official definition** of digital signature.

SELECTIVE forgery

Attacker has the ability to choose M prior to the attack. Selective forgery → Existential forgery

UNIVERSAL forgery

Attacker can produce a valid signature for any given message → Selective → Existential

→ Existential → → Selective → → Universal. Preventing Existential forgery we prevent them all.

Practically Alice sends $(M, S, \text{certificate})$ where the certificate guarantees that the public key is associated to Alice. Used schemes are RSA, El-Gamal signature scheme and **Digital Signature Standard** (modification of El-Gamal)

RSA

Signature is a code hash of message using private key → only who know private key can sign. Everybody can verify using public key.

Public Key Crypto Standard: signature is called digest

$0 \parallel 1 \parallel$ at least 8 bytes FF base 16 $\parallel 0 \parallel$ specification of used hash function $\parallel \text{hash}(M)$

↓ denotes signature (if z, encoding)

↓ increase security

encoded message less than n

11111111 = encoded message longer

SSA: signature scheme with Appendix, the appendix is the signature added to the message.

ELGAMAL SIGNATURE SCHEME

In addition to private/public key pair, will be generate a second temporary pair for digital signature.

p = prime of 1024 bits which discrete log hard in \mathbb{Z}_p^* g = generator of \mathbb{Z}_p^* $x = \text{random}[z, p-2]$ $y = g^x \pmod{p}$
→ public Key = (p, g, y) , Private Key = y p and g not always in public key but always not secret

Plus for signing M :

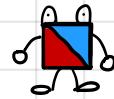

$m = H(M)$, $K = \text{random}[1, p-2]$ relatively prime to $p-1$, $r = g^K \pmod{p} \leftarrow$ not depending on M

$S = (m - r)x \pmod{p-1}$ (if $s=0$ restart)

⇒ Signature = (r, s)

Verify M, r, s, p, K :

(compute $m = H(M)$). Accept if $(0 < r < p) \wedge (0 < s < p-1) \wedge (y^r r^s = g^m) \pmod{p}$

DIGITAL SIGNATURE STANDARD (DSS)

Inspired by Elgamal and uses SHA as hash function and DSA (algorithm) as signature

$p = L$ bit prime s.t. discrete log mod p is hard. $q = 160$ bit prime divides $p-1$: $p = 3q + 1$

[d] s.t. $d^q \equiv 1 \pmod{p}$

↳ $h = \text{random number}$ s.t. $1 < h < p-1$ $g = h^{(p-1)/q} \pmod{p} = h^3 \pmod{p}$ (if $g=1$ try again, too insecure)
 $\Rightarrow g^q \equiv h^{p-1} \equiv 1 \pmod{p}$

Fermat's theorem: $h^{p-1} \equiv 1 \pmod{p} \rightarrow p$ is prime $\rightarrow d = g$

DSA: p prime, q prime, $p-1 \equiv 0 \pmod{q}$, $d = 1^{1/q} \pmod{p}$

Private key = secret s between 1 and $q-1$ random

Public key = $(p, q, d, y = d^s \pmod{p})$

Signing M :

- choose random $1 \leq k \leq q-1$ secret
- $P_I = (d^k \pmod{p}) \pmod{q}$
- $P_{II} = (\text{SHA}(M) + s \cdot P_I) K^{-1} \pmod{q}$

P_I independent from M ,

Signature (P_I, P_{II})

Verify:
 $e_1 = (\text{SHA}(M) / P_{II}) \pmod{p}$ Accept if: $(d^{e_1} y^{e_2} \pmod{p}) \pmod{q} = P_I$ **Proof on slides!**
 $e_2 = (P_I / P_{II}) \pmod{q}$

Finding p and q are hard to find so p and q are generally public
Slower for verification than RSA but faster in signing with preprocessing.
Both admissible.

TIMESTAMPING DOCUMENT

Timestomping Authority (TSA) guarantees timestamp of a document.

Alice wants to timestamp her doc.

- $H(\text{doc})$ to TSA
- TSA add timestamp, $H(H(\text{doc}) + t)$ and signs it, then sends it to Alice
- Alice keeps TSA's signature as proof.

Everybody can verify it, TSA doesn't know Alice's doc, only its hash!

TRUSTED PARTY

KDC = Key Distribution Center

Not possible to have a secret key for every pair of users.

↙

Trusted Party: every user share a key with the trusted authority C (authentication server). Note: "user" can be printer, database etc that need authentication.

Eg. A and B share a key with C → K_{AC} and K_{BC}

Goal: A and B must authenticate and choose a secret session key K used for short time (session) known only by A, B and C

① A sends to C: $[A, B]$

② C chooses K session key and sends to A: $[K_{AC}(k), K_{BC}(k)]$

③ A decodes and compute K and sends to B: $[C, A, K_{BC}(k)]$

④ B decodes $K_{BC}(k)$ finding K and sends to A $[K(\text{Hello } A, \text{Im } B)]$ → now both they have K.

 Man in the middle can intercept messages and substitute C with himself!

1) A: $[A, B]$ to T instead of C

2) T: $[A, T]$ to C

3) C: $[K_{AC}(k), K_{TC}(k)]$

4) A: $[C, A, K_{TC}(k)]$ to B → T intercepts

5) T: $[K(\text{Hello } A, \text{Im } B)]$ to A → A thinks T is B → solve with A: $[A, K_{AC}(B)]$ to C to hide the destination to T

↓

Still can be attacked: T intercepts at ① and send to C $[A, K_{AC}(T)]$ T doesn't know the real destination.

A will send to B: $[C, A, K_{TC}(k)]$ → T finds that A wants to talk to B and then it acts like B: $[K(\text{Hello } A, \text{Im } B)]$ to A

Now T knows B.

Protocol Needham - Schröder: uses "nonce" = random numbers.

1) A chooses N (nonce) and sends $[A, B, N]$ to C

2) C chooses K and sends $[K_{AC}(N, K, B, K_{BC}(K, A))]$ to A

3) A decodes and checks N and B and sends $[K_{AC}(K, A)]$ to B

4) B decodes, chooses N' and sends $K(\text{this is } B, N')$ to A

5) A sends $[K(\text{this is } A, N'-1)]$ to B → B now has checked A!

↓

Attack: At point ② T acts as A, at ③ T sends $[K_{AC}(K', A)]$ to B instead of $[K_{BC}(K, A)]$ where K' = old session key.

B responds, T intercepts $[K'(\text{this is } B, N')]$ and T sends $[K'(\text{this is } A, N'-1)]$ to B

Note: T must have K' and B never talk to C!

To guarantee data integrity use timestamps, sequence numbers or nonce (nonce should be used carefully)
Sole nonce only for limited time → don't reuse.

KERBEROS: provides authentication in distributed systems

Scenario: A needs to access service of B → Need authentication of A (optional: auth. B and generate session key), use C → Idea = use ticket to access services, valid for limited time.

Each user is called principal and has a secret key shared with KDC stored in KDC and encrypted with KDC's key.

Kerberos makes use of "tickets": a message that only the destination can decrypt containing the key that will be shared between A and B, A's identity e.g. $[K_B(K_{AB}, \text{"Alice"})]$. Of course the ticket is "generated" by KDC. B can be a service too. Ticket has a lifetime (duration of permission of access) and timestamp to avoid reuse.

Messages and requests from A to KDC must be encrypted each time with K_{AC} → ztype everytime or store it ^{Never!} → inadequate

⇒ **Ticket-granting Ticket (TGT)**: use a metaticket used to ask the real ticket.

- At first login A receive a session Key S_A by KDC, with fixed lifetime (few hours), and other infos.
- Next requests from A to KDC will contain TGT
- No need to store "real" password.

Problems:

- different servers must have synchronized clocks cause of timestamp system to avoid **replay attack**.
- authenticator does not guarantee data integrity
- many instances of some servers use same master key → replay attack.

Generally there are many instances of some KDC with some KDC with a single one that store infos and then uploads to others periodically.

In large networks systems, the network is divided in subnetwork called **realm**s. Each of them has different KDC master with some master key. Different KDC in different realms have different users databases. Anyway every user can talk with users in different realms just talking first with the specific KDC of the destination realm.

AUTHENTICATION USING PUBLIC KEY (Needham-Schroeder)

Idea: sign messages containing timestamp with public key → problem: where to store the key?

⇒ third trusted party C

How? A want to talk with B → tell it to C that will responds with $\langle B, \text{sign}_C(K_{PB}, B), K_{PB} \rangle$

A check the signature, generate Nonce and sends to B $\langle K_{PB}(N, A) \rangle$

Now B wants to check A's identity → $\langle B, A \rangle$ to C → C to B $\langle A, K_{PA}, \text{sign}_C(K_{PB}, A) \rangle$

B check signature, retrieve K_{PA} , generate N' and sends to A $\langle K_{PA}(N, N') \rangle$. A check N and sends to B $\langle K_{PA}(N) \rangle$

Attack: T can talk with A,B,C with authentication between A and T (R_1) and between T (as A) and B. (R_2)

In R_1 we have $K_{PA}(N, A)$. In R_2 $K_{PB}(N, A)$ and then B sends to T $K_{PA}(N', N)$. T → A $\langle K_{PA}(N', N) \rangle$ in R_1 and then

A → T $K_{PA}(N')$. In R_2 T → B $\langle K_{PB}(N') \rangle$ ⇒ Now B thinks he is talking to A!

⇒ **Fix**: B sends to A $\langle K_{PA}(B, N, N') \rangle$ and not only $\langle K_{PA}(N, N') \rangle$ forbidding T to use it and send it to A.

PUBLIC KEY INFRASTRUCTURE (PKI)

Certificates are issued by a trusted Certification Authority (CA) for all users in domain. If A wants B's public key it ask to CA that responds with the key signed with its own private key → A must know only one key: CA's public key.

X.509

- Serial Number: unique in each CA's domain
- Issuer: the X.500 name of the issuing CA. (country, organization etc)
- Validity: time interval of duration for the certificate. Not valid for signing after expiration, but valid to verify old signatures.
- Subject: X.500 name of who own the public key.
- SubjectPublicKeyInfo: algorithm identifier used for the key and subject's public key.
- and many more...

NB. Impossible to falsify. If A and B share some CA they can know each other public key. Otherwise CA form a hierarchy. → 3 levels

Level 1 = root certification authority → self signing

REVOCATION (before deadline)

Reasons:

- ① User's secret key not safe anymore or lost
- ② User is not certified by CA
- ③ CA's secret key compromised.

After certificate check, a revocation check must be done.

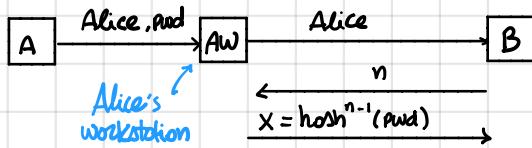

Exp. date → Digital Signature → revocation check

ONLINE CERTIFICATE STATUS PROTOCOL used to get revocation status of X.509 certificates.

PASSWORD

To avoid eavesdropping and the possibility that an attacker broke the password database we store data obtained from password (hash). User password is attached to salt to avoid dictionary attack and then converted to a 56 bit secret key K and then stored $\text{desc}(\text{desc}(\dots \text{desc}(\dots \text{desc}(\dots \text{data}))\dots))$. For authentication we must avoid eavesdropping, MITM and dictionary attacks → strong protocols: cryptographic authentication with user remembering only personal password.

LAMPORT'S HASH

Bob stores $\langle \text{username}, \text{large number } n, h^n(\text{password}) \rangle$

Alice's workstation sends $x = h^{n-1}(\text{password})$

Bob computes $h(x)$: if successful, n is decremented, x replaces h^n in Bob's database

In addition we can add salt to password, stored at Bob's setup time guaranteeing to Alice to use the same password with different servers (different salts)

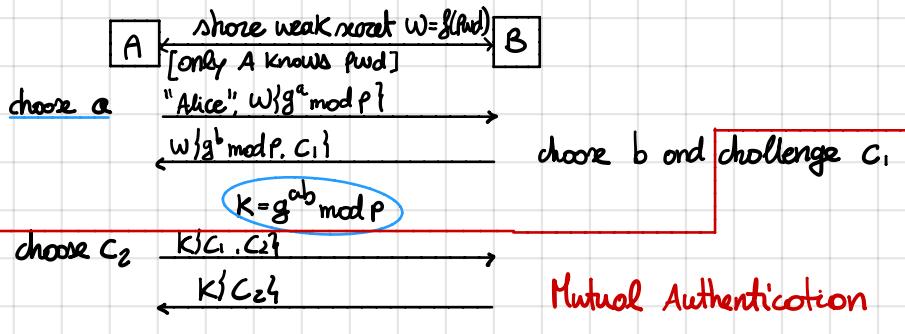

Small n attack: Trudy impersonates Bob and sends $n' < n$ and salt, when she gets the reply she can impersonate Alice until $n = n'$.

Defense: AW shows submitted n to A to verify the approximated range → A needs to remember it.

"Human and paper" env.: if AW is insecure and too dumb to do hashing, A is given a list of all hashing from n and she uses them exactly once each preventing small n attack.

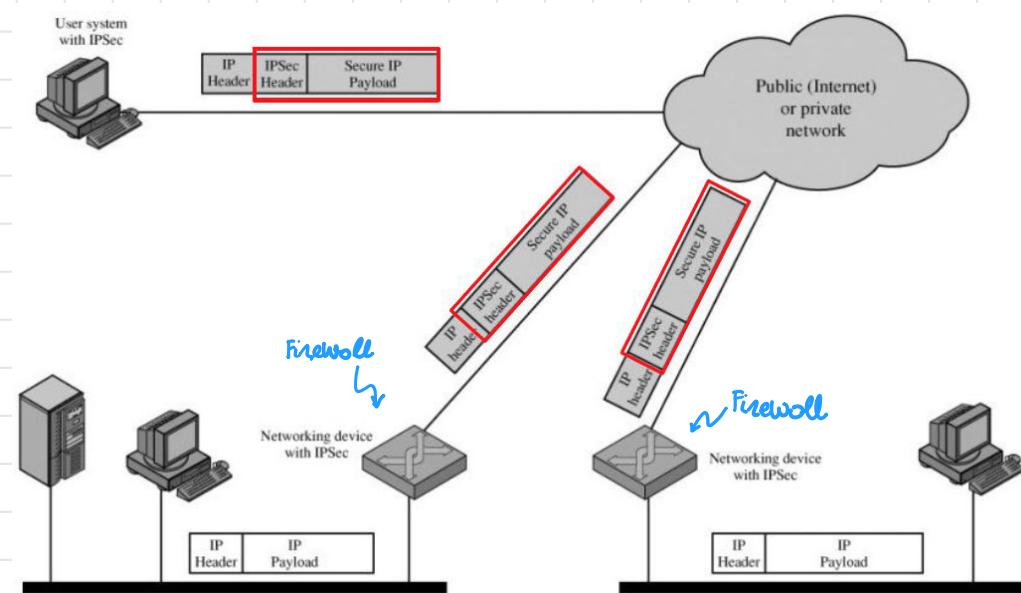

EKE: encrypted Key exchange

To avoid dictionary attacks if weak keys are chosen. It guarantees mutual authentication with session keys.

IPSEC

IP security : provide security between IP and TCP . Security protocol that can be used by all applications. Provides authentication, confidentiality and key management . Applicable over LANs, public and private WLANs and internet . Very complicated.

Using IPsec a firewall/router can provide security to all traffic crossing the border, resistant to bypass and can be used even on individual users. Works below transport layer → transparent to applications. Main feature is encrypting and/or authenticating traffic at IP level. securing all distributed applications.

It is implemented as additional header:

Authentication header (AH) : header for authentication

Encapsulating Security Payload (ESP) : header for encryption.

- Access control : prevents unauthorized use of a resource
- Connectionless integrity : detect edit of individual IP datagram
- Data origin authentication : verify identity of data's source
- Rejection of replayed packets : partial sequence integrity
- Confidentiality (encryption)
- limited traffic flow confidentiality : TFC = concealing source and destination addresses, message length or frequency of communication.

AH ESP (no auth.) ESP (with auth.)

Access control	✓	✓	✓
Connectionless integrity	✓		✓
Data origin authentication	✓		✓
Rejection of replayed packets	✓	✓	✓
Confidentiality		✓	✓
Limited traffic flow confidentiality		✓	✓

SECURITY ASSOCIATIONS

SA are one-way relationship between sender and receiver. There are databases for SAs (SADB) dividing inbound and outbound connections for each interface with IPsec enabled.

SA is denoted by: Security Parameters Index (SPI), IP Destination Address and Security Protocol Identifier (AH / ESP).

For every bidirectional connection we have a pair of SAs. SPI is a sort of TCP port number that allow receiver to select in which SA will process a packet. For multicast, SA is provided for the group and duplicated for all authorized receiver. May be multiple SA for single group to add multiple layer of security.

SA Selector: filter traffic in order to map it into a particular SA of SPDB.

SPDB is a database that specify the policies that determine the disposition of all IP traffic even if not IPsec while SADB contain SAs parameters (eg. encryption key)

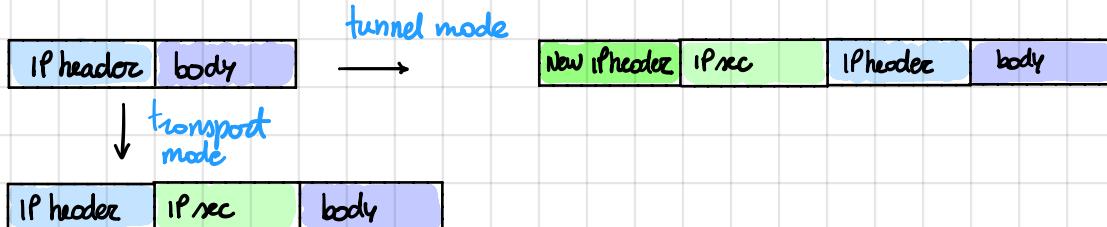

SAs can work in **transport or tunnel mode** according to the fact that the authentication is end2end or end2intermediate (eg router)

TRANSPORT MODE

Original IP header untouched, IPsec infos added between IP header and body. Used for host-to-host communications. Routing intact since only payload is encrypted and/or authenticated

TUNNEL MODE

Keep original IP packet intact but protect it adding new header. → New IP packet. Usually used to create VPN.

	Transport Mode SA	Tunnel Mode SA
AH	Authenticates IP payload and selected portions of IP header and IPv6 extension headers.	Authenticates entire inner IP packet (inner header plus IP payload) plus selected portions of outer IP header and outer IPv6 extension headers.
ESP	Encrypts IP payload and any IPv6 extension headers following the ESP header.	Encrypts entire inner IP packet.
ESP with Authentication	Encrypts IP payload and any IPv6 extension headers following the ESP header. Authenticates IP payload but not IP header.	Encrypts entire inner IP packet. Authenticates inner IP packet.

As we said SAs can implement both AH and ESP in two ways:

- **transport adjacency**: apply more than one protocol to same IP packet without tunneling, only one level of combination.
- **iterated tunneling**: apply multiple layers of security with multiple tunneling.

The two methods can be combined.

In order to have both encryption and authentication there are 3 ways.

1) ESP with authentication

User first applies ESP and then append authentication data field.

- (1a) transport mode: auth. and encr. to IP payload but IP header is not protected] authentication
- (1b) tunnel mode: entire inner IP packet is protected, all IP packet authenticated.] after encryption

2) Transport adjacency:

Still authentication after encryption. Uses two bundled transport SAs: ESP (inner) and AH (outer)

Encryption applied to IP payload and resulting packet is IP header + ESP. Then AH is applied in transport mode → auth. covers ESP + original IP header

3) Transport-Tunnel Bundle

Authentication before encryption: authentication data encrypted → impossible to alter them
+ if message stored as plaintext then verifying authentication data doesn't require re-encryption.

Inner AH in transport mode and outer ESP in tunnel mode: authentication applied to IP payload + IP header, then all processed in ESP tunnel mode, resulting in an authenticated inner packet encrypted + new IP header.

How SSL/TSL WORKS

Under Application level and over TCP to be used with HTTP → [HTTPS](#).

Offers interface to securely send packets (delivery guaranteed by TCP).

Handshaking between client and server, server picks strongest cipher and hash function available for both and notifies client of the decision. → Timeconsuming → Many webmasters don't use TLS for this reason ([Wrong](#))

Server sends its identification (x.509 certificate) and client can check with CA.

Client generates session key creating a random number (RN) encrypted with server's public key (Pbk) the only one who can decrypt it with its private key (Pk).

Client knows Pbk and RN and server knows Pk and RN: from RN both can encrypt and decrypt.

If one of previous steps fails → connection closed.

Typically authentication is unilateral (only server) even though is possible to have bidirectional (require certificate in server side too)

Session ≠ connection. A session (made by handshaking) can have multiple (peer-to-peer) connections which are persistent in the session.

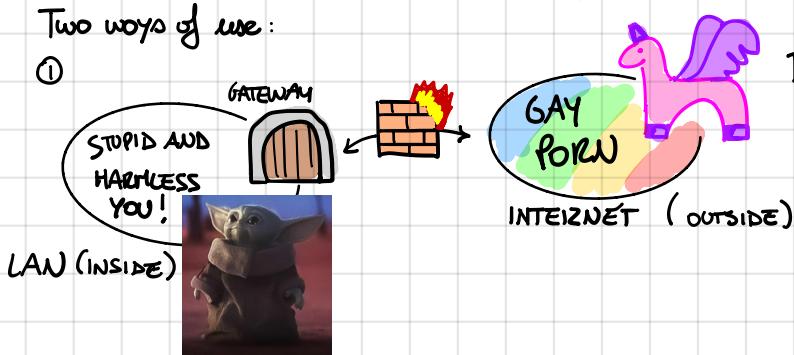

Between any pair of parties there may be multiple secure connections.

FIREWALLS

Separate local network from internet. It is an additional security system (hardware or software) that can be used with or without cryptography etc.

Two ways of use:

①

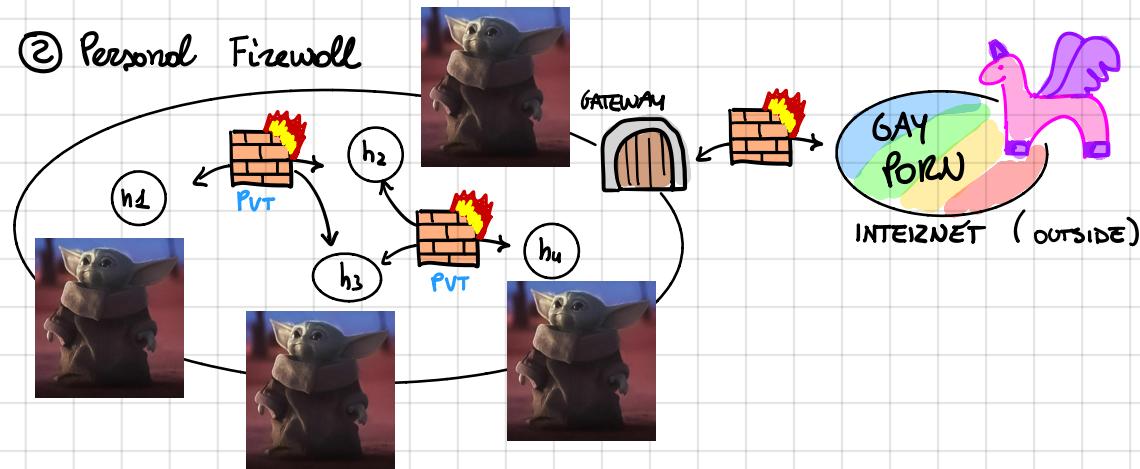

Firewall works as a **packet filter**.

↳ Stateless → without memory.

• Statefull → **connection filtering**: store info about connections (associated with packets)

Firewalls can work at **application level** analyzing HTTP messages (**FIREWALL PROXY**)

② Personal Firewall

IPTABLES

Used (in Linux) to maintain tables of IPv4 packet filter rules. These tables contain the so called **chain**, list of rules which can match set of packets.

Example of built-in chains are **INPUT**, **OUTPUT** (for personal firewalls mostly) and **FORWARD** (for perimeter firewall)

Examples:

1) `iptables -A FORWARD -i eth0 -j DROP`

-A: append the following rule to table

FORWARD: specify that we are using rules for perimeter firewall and not for local delivery

-i: input interface (eg eth0)

-j: target

DROP: discard packet without notification

→ Block all INCOMING traffic.

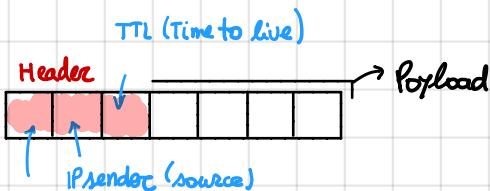

2) `iptables -A FORWARD -i eth0 -m state --state ESTABLISHED -j ACCEPT`

-m state: add module state

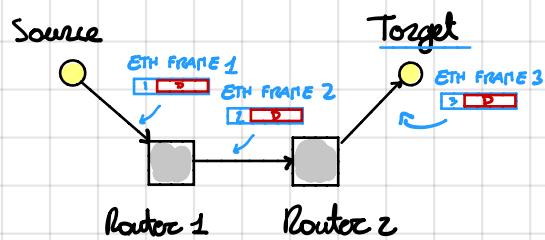

--state ESTABLISHED: specify state module settings

ACCEPT: accept packets

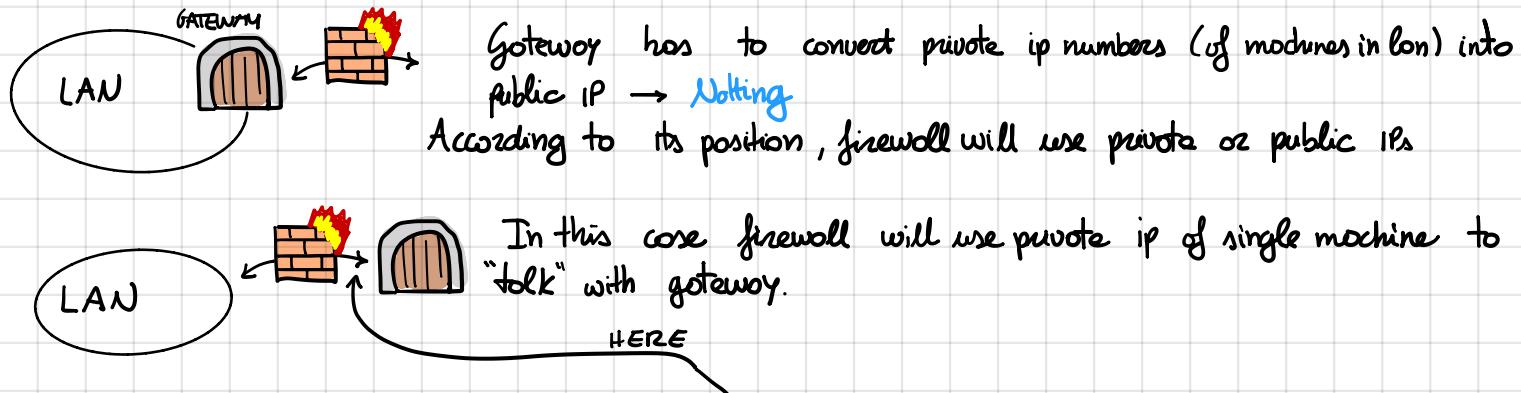

→ Accept packets from outside if they refer to a TCP connection started within the network (ESTABLISHED means that)

Target: public IP number of target (not routers between)

Datagram is inserted in Ethernet frame which has two new source and target to move the datagram across routers. (Source - R1, R1 - R2, R2 - Target)

In case of attack we want to block all packets incoming:

IPTABLES - I 1 FORWARD -i eth0 -j DROP

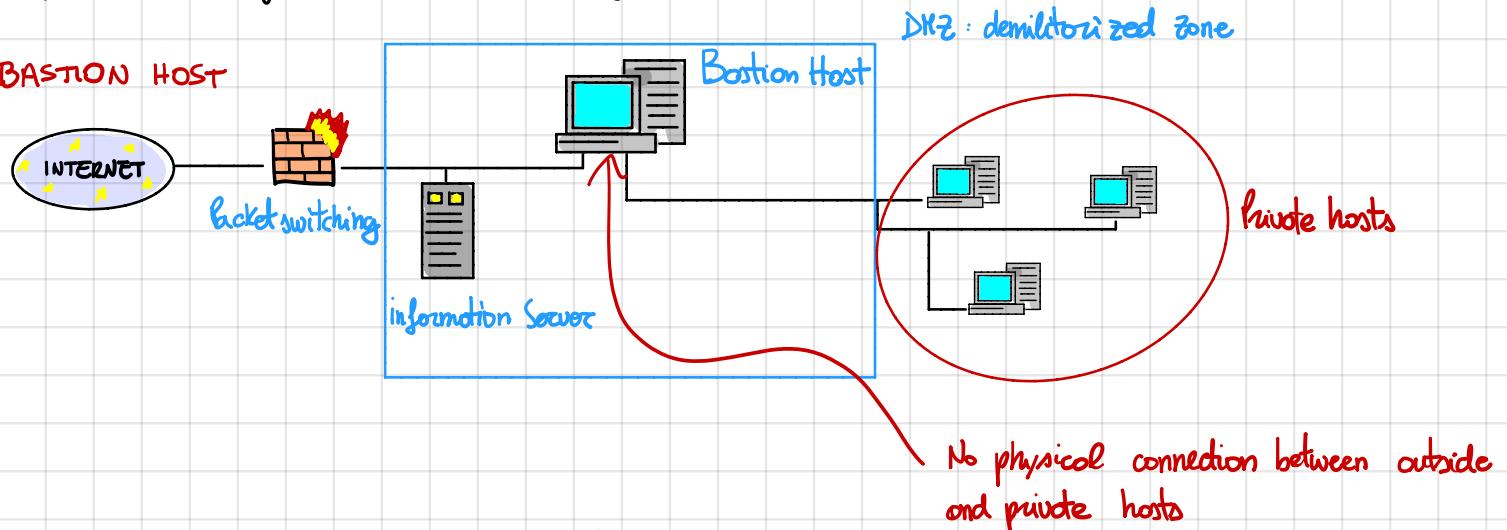

IPTABLES - I 2 FORWARD -o eth0 -j DROP

important to put at beginning both

SUICIDE RULE: IPTables -I input -dport 22 -j DROP → need to access manually to firewall
↳ # omitted = 1
no more SSH

As we said, firewalls can work at application level and today is the most used/powerfull approach.

APPLICATION LEVEL GATEWAY (firewall): it works as proxy for different protocols, adding new one is complex though. A firewall doesn't ensure confidentiality anyway!

Bastion host is super secure and protected, no unneeded software or compilers. Only read system. Process and integrity checker

A similar solution is to add another firewall between bastion host and private hosts: SCREENED SUBNET
